OBJECTS AND CLASS DESIGN

Today

- We will start to talk about *object-oriented programming*
- In particular we will talk about struct and class.
- We will show how to use these features of C++ to define aggregate data types.
- We will show how to define *methods* that operate on these data types.
- This work is based on Pohl, Chapter 4.
- Much of the work we will do for the next couple of weeks will be concerned not only with what we can do in C++, but also the *style* in which we do it.

Aggregate data types

- New today: class and struct
- struct comes from C
- class is new in C++
- Both are aggregate types, meaning that they group together multiple fields of data.
- For example:

```
struct point {
   double x, y;
};
```

• Don't forget to put a semi-colon at the end of the structure definition!

Aside: why is point useful?

- The idea behind point is that it represents information about the location of something.
- Think of it as a pair of (Cartesian) coordinates.
- We group the coordinates together because they make no sense separately if we have the x coordinate of a thing, then it has a y coordinate also.
- We will use point when we write a simulation of small eco-system. We will do this in some of the homeworks.

Back to aggregate data types

- In C, the tag (point) is optional and does not constitute a data type (you need to use typedef as well).
- In C++, the tag is considered a data type, hence the above example is a data type definition.
- This means that you can use point as a data type, e.g.: point p;
- In other words, you can declare a variable p which is of type point.

- The fields or elements of an aggregate data type are called *members*.
- Members are referred to using "dot notation", e.g.:

p.x = 7.0; p.y = 10.3;

• You can also use a *pointer* to access members of an aggregate data type, e.g.:

p->x = 12.3;

but we will discuss pointers in the next unit, so don't worry about this now...

• The fields or elements of an aggregate data type are called *members*.

• You can also declare a structure and a variable of that type in the same statement, e.g.:

```
struct {
   double x, y;
} myPoints[3] = { {1, 2}, {3, 4}, {5, 6} };
```

defines the array myPoints to hold three elements each of which is a struct which holds two doubles, and sets the values of these.

• This is not the clearest way of doing things. I would prefer:

```
struct point {
   double x, y;
};
```

```
point myPoints[3] = { {1, 2}, {3, 4}, {5, 6} }
```

Member functions

- In C++, members of aggregate data types can be functions
- (C only allows data members)
- In object-oriented programming (OOP) lingo, the word "method" is often used instead of "function"
- The reason to define functions inside an aggregate data type is to follow the OOP principle of *encapsulation*—operations should be packaged with data
- This is a *style* thing.
- For example:

```
#include <iostream>
using namespace std;
struct point {
  double x, y;
 void print() {
    cout << "(" << x << "," << y << ")\n";
 void set( double u, double v ) {
   x = ui
    y = v;
}; // end of struct--don't forget semi-colon!
int main() {
 point w;
 w.set( 1.2, 3.4 );
 cout << "point = ";</pre>
 w.print();
```

• Notes:

- Notice that the set method changes the values of the data members—this is considered good OOP practise
- Defining the methods inside the struct definition is called "in-line declaration"; this is generally only okay for short, concise methods
- The *class scope* operator can be used when in-line declarations are inappropriate.
- For example:

```
#include <iostream>
using namespace std;
struct point {
 double x, y;
 void print();
 void set( double u, double v );
};
void point::print() {
  cout << "(" << x << "," << y << ")\n";
} // end of print()
void point::set( double u, double v ) {
 x = u;
 y = v;
} // end of set()
```

```
• The methods can then be invoked from main, just as before:
```

```
int main() {
   point w;
   w.set( 1.2, 3.4 );
   cout << "point = ";
   w.print();
} // end of main()</pre>
```

Public and private access

- Members of structures can be public or private
- public means that any code can access the members
- private means that only code inside the class or struct can access the members (or "friend" classes, to be discussed later in the term)
- Typically, following good OOP practice, all data members are private and only function members are public (but not all—only those that need to be accessed outside of the struct or class).

```
• For example:
```

```
struct point {
public:
    void print();
    void set( double u, double v );
private:
    double x, y;
}; // end of struct--don't forget semi-colon!
```

(the rest of the example code is the same as the previous one)

"class" vs "struct"

• The difference between structs and classes is:

- In a struct, the members are public by default

- In a class, the members are private by default
- For example:

```
#include <iostream>
using namespace std;
class point {
  double x, y;
public:
 void print();
 void set( double u, double v );
}; // end of struct--don't forget semi-colon!
void point::print() {
  cout << "(" << x << "," << y << ")\n";
} // end of print()
void point::set( double u, double v ) {
 x = u;
 y = v;
} // end of set()
```

• main looks the same as before:

```
int main() {
   point w;
   w.set( 1.2, 3.4 );
   cout << "point = ";
   w.print();
} // end of main()</pre>
```

- In this example, x and y are private and the methods are public.
- Otherwise, class and struct are the same
- But by convention, C++ programmers tend to use class

Class scope

• The class scope operator is two colons (::), as in our example:

```
void point::print() const {
   cout << "(" << x << "," << y << ")\n";
}</pre>
```

- The :: operator has the highest precedence in the language, so it always gets evaluated first
- There are two versions of the operator: binary and unary
- The binary version is the one we used before: point::print(), which is used to refer to a variable's "class scope" (also called "local scope").
- The unary version is like this: ::count and is used to refer to a variable's "external scope" (e.g., for a global variable).

```
• Here is a (maybe) confusing example from the book:
```

```
int count = 0; // declare global variable
```

```
void how_many( double w[], double x, int& count ) {
  for ( int i=0; i<N; ++i ) {
    count += ( w[i] == x ); // local count
  }
  ++::count; // global count
} // end of how_many()</pre>
```

- This is only necessary since count is declared twice
- If you didn't have the ::count, then the second time, it would also refer to the local variable
- It is better practise not to use global variables; or at least if you do, give them unique names to avoid confusion :-)

Nested classes

- Classes can be nested one class is placed inside another.
- Here's another confusing example from the book:

```
char c; // global scope

class X {
  public:
    char c; // local scope in class X
    class Y {
      public:
         void foo( char e ) { X t; ::c = t.c = c = e; }
        private:
            char c; // local scope in class Y
      };
};
```

- The scope of the first c is ::c.
- The scope of the second c is X::c.
- The scope of the third (last) c is X::Y::c
- The inner class, Y can only be referenced from within X.
- So, you can only create instances of Y within Y, you can only access even the public the data members of Y from within X.
- If this sounds overly confusing, then don't worry.
- You should be able to write all the programs you need *without* using nested classes.

- The keyword this is used to refer to an instance of a class from within itself.
- It is a *pointer* something we will discuss at length in the next unit
- For example:

```
point inverse() {
    x = -x;
    y = -y;
    return (*this);
}
```

- In this example, the function returns a pointer to the object that is calling it
- We'll come back to this when we discuss pointers

"static" members

- The keyword static is used to refer to data members of a class that are the same across all instances of the class.
- In other words, it is independent of any class variable
- For example in the following program, a.dimensions and b.dimensions both have value 2.

```
class point {
      public:
         static int dimensions;
         •
         .
    };
    int main() {
       •
      point::dimensions = 2; // initialize point
      point a, b;
cis15-fall2007-parsons-lectII.1
```

"const" members and "mutable"

- Data members with the const keyword in their definition cannot be modified.
- For example:

```
class point {
   double x, y;
   public:
      const int dimensions = 2;
      void print() const;
};
void point::print() {
   cout << "(" << x << "," << y << ")\n";
} // end of print()</pre>
```

• dimensions cannot be modified.

- Confusingly, you can use the same keyword const along with function members.
- For example:

```
class point {
   double x, y;
   public:
      const int dimensions = 2;
      void print() const;
   };

void point::print() const{
   cout << "(" << x << "," << y << ")\n";
   } // end of print()</pre>
```

• This says that print is not allowed to modify any of the data members of point.

- Without specifying a method as const, it is allowed to alter *any* of the data members.
- Just to confuse the picture even further we have the keyword mutable.
- If, in some class definition, we define:

```
mutable int delta;
```

it means that delta can be modified by *any* method for that class, even if the method is defined as being const.

Special types of classes: "containers"

- There are several special types of classes in C++.
- The first we will discuss is called a *container*.
- It is a class designed to hold large numbers of objects.
- An example of a container is a *stack*, a class which can hold information in such a way that the first thing placed into the stack is the last thing to be removed from the stack.
- Our example will hold characters, and you can find it on the class webpage it is the program basic-stack.cpp.

```
#include <iostream> using namespace std;
    class ch_stack {
      public:
        void reset() { top = EMPTY; }
        void push( char c ) { s[++top] = c; }
        char pop() { return s[top--]; }
        char top_of() const { return s[top]; }
        bool empty() const { return( top==EMPTY ); }
        bool full() const { return( top==FULL ); }
      private:
        enum{ max_len = 100, EMPTY = -1, FULL = max_len -1 };
        char s[max len];
        int top;
    };
cis15-fall2007-parsons-lectII.1
```

```
29
```

```
int main() {
  ch_stack s;
  char str[40] = { "hello world!" };
  int i = 0;
  cout << "str=" << str << endl;</pre>
  s.reset();
  while( str[i] && ! s.full() ) {
    s.push( str[i++] );
  cout << "reversed str=";</pre>
  while ( ! s.empty() ) {
    cout << s.pop();</pre>
  cout << endl;</pre>
} // end of main()
```

Aside: why is stack useful?

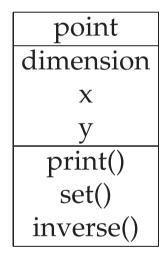

- There are several reasons.
- First, it is the simplest example of a *dynamic* data-structure one where the memory that is uses is determined at *run-time* not *compile-time*.
- You will meet many other kinds of dynamic data-structure in the future, and understanding a stack will help you in understanding those others.
- Second, a *run-time stack system* is a system of memory allocation commonly used on most computers to keep track of how much memory is available to a program and allocates pieces of it as they are needed.

- When a function is called, the memory required for the function (e.g., its local variables) is allocated from (*pushed onto*) the stack; when the function exits, the memory is freed from (*popped off*) the stack
- Thus stacks are fundamental to the way that all computer programs work.

Class design

- Data members should be private ("hidden")
- Function members are often public (but not always—private function members can be used for computations internal to a class).
- Functions that do not modify data members should be const
- Pointers add indirection (we'll talk about that later)
- A uniform set of functions should be included: set(), get(), print()

• UML (unified modeling language) provides a graphical method for representing classes

Summary

- This lecture introduced the basics of object-oriented programming.
- It showed how struct and class can be used to create aggregate datatypes and the methods for those types.
- It discussed public and private methods, and how these should be used in good class design.
- The lecture also looked at static, const and mutable, and mentioned features such as class nesting, and the this pointer.
